ABSTRACT

Variability in the Lower Bowland shale microstructure is investigated here, for the first time, from the centimetre to the micrometre scale using optical and scanning electron microscopy (OM, SEM), X-Ray Diffraction (XRD) and Total Organic Carbon content (TOC) measurements. A significant range of micro-textures, organic-matter particles and fracture styles was observed in rocks of the Lower Bowland shale, together with the underlying Pendleside Limestone and Worston Shale formations encountered the Preese Hall-1 Borehole, Lancashire, UK. Four micro-texture types were identified: unlaminate quartz-rich mudstone; interlaminated quartz- and pyrite-rich mudstone; laminated quartz and pyrite-rich mudstone; and weakly-interlaminated calcite-rich mudstone. Organic matter particles are classified into four types depending on their size, shape and location: multi-micrometre particles with and without macropores; micrometre-size particles in cement and between clay minerals; multi-micrometre layers; and organic matter in large pores. Fractures are categorized into carbonate-sealed fractures; bitumen-bearing fractures; resin-filled fractures; and empty fractures. We propose that during thermal maturation, horizontal bitumen-fractures were formed by overpressuring, stress relaxation, compaction and erosional offloading, whereas vertical bitumen-bearing, resin-filled and empty fractures may have been influenced by weak vertical joints generated during the previous period of veining. For the majority of samples, the high TOC (>2 wt%), low clay content (<20 wt%), high proportion of quartz (>50 wt%) and the presence of a multi-scale fracture network support the increasing interest in the Bowland Shale as a potentially exploitable oil and gas source. The microtextural observations made in this study highlight preliminary evidence of fluid passage or circulation in the Bowland Shale sequence during burial.

1. Introduction

Characterisation of the properties of shales is an essential process in the estimation of their gas and oil resource potential. Important shale gas and oil resources are believed to exist in Western Europe (EIA, 2013) and in particular in the UK (EIA, 2015a). In order to understand and quantify the properties of this potential resource, the geology of the Bowland and Hodder mudstone formations has been investigated throughout the last decades at the basin-scale (Gawthorpe, 1987; Davies et al., 1989; Hampson et al.,

1997; Fraser and Gawthorpe, 2003; Waters and Davies, 2006; Davies, 2008; Waters and Condon, 2012; Andrews, 2013), and more recently at the nanometre scale (Ma et al., 2016). In general, the most commonly investigated properties of shale have been the lithology, sedimentary architecture, total organic carbon content (TOC), kerogen type, thermal maturity and oil and gas expulsion potential, the mineralogical composition, diagenetic conditions and the presence of natural fracture networks (Curtis, 2002; Rossi et al., 2002; Montgomery et al., 2005; Jarvie et al., 2007; Ross and Bustin, 2007, 2008; Perri, 2008; Caracciolo et al., 2013; Jarvie, 2014; Abrams, 2014; Raji et al., 2015; Perri et al., 2008, 2016). The evaluation of shale resources is complicated because of the heterogeneous nature of the fine-grained strata and their intricate, small-sized pore networks, which are strongly

dependent on the above geological factors (Yang and Aplin, 1998; Dewhurst et al., 1999a, b; Ross and Bustin, 2007; Chalmers and Bustin, 2007; Mckernan et al. 2017). From the millimetre to the nanometre scale, shale gas is stored as free gas in natural fractures, within both intergranular and intra-granular porosity and adsorbed onto kerogen and clay-particle surfaces. It may also be dissolved in kerogen and bitumen (Curtis, 2002). The microstructure directly influences the distribution of gas and its transport properties through the porous network. Knowledge of the microstructure of shale is consequently required. However, there is still a very limited understanding of the processes giving rise to pore networks, fractures, and organic and mineral properties in British Shales. In particular, data are sparse for the Bowland and Hodder Shales, despite forming an important potential oil and gas resource. Detailed petrographic studies of these shales are required to allow a better comparison with other shale formations, especially the relatively well understood shale reservoirs from northern America.

The major goal of this study is to present the first multi-scale (centimetre to micrometre) and petrologic characterisation of the different microtextures of Bowland shale encountered in the Preese Hall-1 borehole, a significant and recent exploration borehole in Lancashire, NW England, using optical and scanning electron microscopy in combination with XRD and TOC analysis. Due to the coarse resolution of sampling within our study, we recognize that potential stratigraphic variability between samples implies that microtextures other than those identified in our study could potentially be present within the borehole.

2. Geological settings and sampling

In this study, eleven centimetric-sized samples of mudstone were collected from the Preese Hall-1 borehole core repository at the British Geological Survey (Nottingham, UK). Preese-Hall-1 is situated in the Carboniferous basin Bowland Shale Formation, which extends across a large part of central Britain (Fig. 1). Drilling of the Preese Hall-1 borehole was initiated in August 2010. It is situated on the Fylde coast of NW Lancashire at $53^{\circ} 49' 19.006''\text{N}$; $2^{\circ} 56' 56.576''\text{W}$, near to Blackpool, north-west England.

Preese Hall-1 is the first dedicated unconventional shale gas borehole in the UK and Europe (De Pater and Baisch, 2011), and was drilled to a depth of 2745 m. Preliminary hydraulic stimulations of this borehole were performed by Cuadrilla Resources Ltd in 2011 (Eisner et al., 2011; De Pater and Baisch, 2011; Clarke et al., 2014).

Within the Bowland basin, the rocks of the Bowland-Hodder group encountered in the Preese Hall-1 borehole are divided into an upper unit characterised by some 150 m of shale (Upper Bowland Shale) and a lower, more variable unit (Lower Bowland Shale) containing almost 500 m of shale interbedded with clastic and carbonate deposits due the influence of glacio-eustatic sea level changes and tectonic events (Gawthorpe, 1987; Andrews, 2013). The Bowland Shale Formation (Upper and Lower Bowland shales) corresponds to ages between the end of the Visean (Brigantian) and the beginning of the Namurian (Pendleian) (Waters et al., 2009) (Fig. 2). The Pendleside Limestone Formation lies below the Bowland Shale Formation and marks the bottom of the Bowland Shale sequence (Waters et al., 2009). Beneath, the Worston shale group forms a further 150 m thick unit of shales. The top of the Bowland shale group passes into the Millstone Grit Group (Pendleian). The Bowland shale, Pendleside limestone and Worston shale are all included in the Bowland-Hodder Unit corresponding to the whole Visean period (Andrews, 2013).

The samples used for the present study were taken predominantly (Fig. 2) from the lower Bowland Shale Formation (samples B1 through B10). Sample B11 was taken from the Pendleside limestone Formation and B13 from the lower part of the Worston

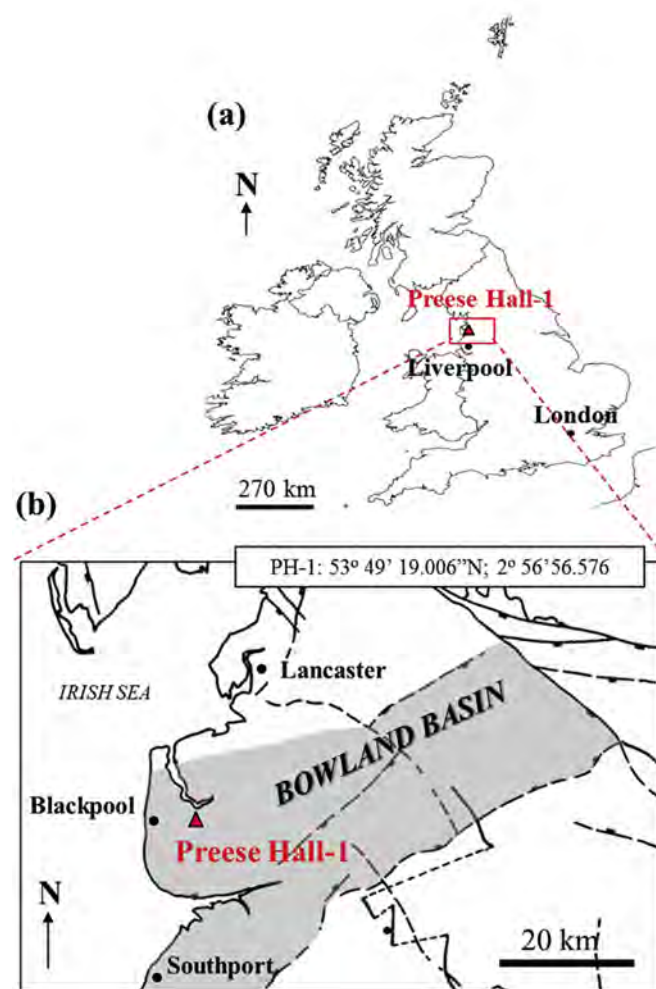

Fig. 1. Location of the Preese Hall-1 borehole in: (a) the United Kingdom and (b) the Bowland Basin (adapted from Evans and Kirby, 1999; mapsofworld 2015).

Shale Formation (there is no B12).

In general, the organic content of the Bowland Shales lies between 1 and 3 wt% (Spears and Amin, 1981; USEIA, 2011), but can reach 5–8% (IGas, 2012; Andrews, 2013; EIA, 2015a,b).

3. Material preparation and methods

The mineralogy of all samples was semi-quantified by X-Ray diffraction (XRD) on a Bruker D8 Advance diffractometer, equipped with a Göbel Mirror and Lynxeye detector. The X-ray tube provided $\text{CuK}\alpha_1$ X-rays with a wavelength of 1.5 Å. Sample preparation involved grinding ~0.1 g of sample material mixed with ~1 ml of amyl acetate. Samples were scanned between 5° and $70^{\circ} 2\theta$, with a step size of 0.02° and a count time of 0.2s per step. The resultant patterns were evaluated using EVA 113 version 4, which compares experimental data to standards from the ICDD (International Centre for 114 Diffraction Data) Database. The standard deviation of mineral eight proportions is in the range of a percent.

Total organic carbon (TOC) was measured with an experimental uncertainty of $\pm 0.02\%$ TOC using 100 mg powder samples in a Leco carbon analyzer (Michigan, United States) at the University of Newcastle (UK), after rock acidification and organic matter combustion.

All samples were vacuum impregnated with epoxy resin and

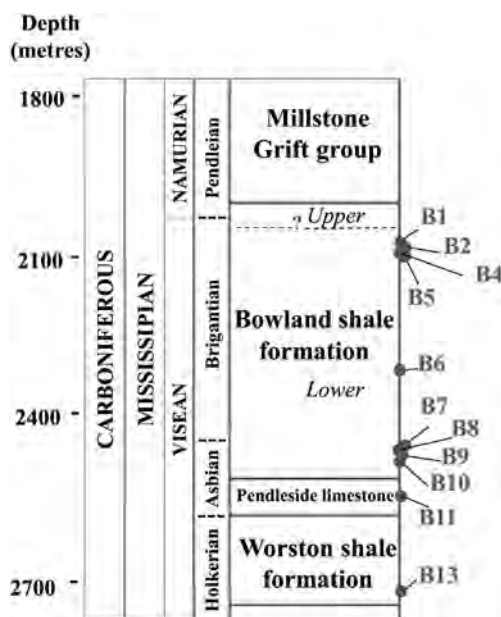

Fig. 2. Bowland basin stratigraphy in the Preese Hall-1 borehole, showing the stratigraphic locations of the samples studied, which lie within the Bowland-Hodder group.

mechanically polished as thin sections for optical and scanning electron microscopy. Optical microscopy was performed using an Olympus SZX16 stereomicroscope to obtain low magnification images of the general textures from cm-to mm-scale. Low magnification observations were also made with a JEOL JSM 6610LV SEM equipped with a back-scattered electron detector and semi-quantitative EDS analyzer. The accelerator voltage was 20 kV and the working distance 10 mm. To confirm the nature of minerals, EDS point analysis and mapping was used with AZtec[®] software. High magnification observations were performed with a SEM FEI Quantax FEG 650, with an accelerator voltage of 10 kV. Apart from macropores, pore types are not described here because of the resolution of the study. The differentiation between impregnation resin and organic matter under SEM was achieved using a combination of three criteria:

- the morphology: organics have smooth faces at boundaries, whereas resin has clear boundaries with the material due to its viscosity. The resin contains clear cracks at some places, formed by the local heating by the electron beam at high energy (20 kV).
- the peak intensity of carbon in EDS analysis. In our case, the organic matter particles show a peak of carbon for energy much higher than 15 cps. eV⁻¹, in contrast to the resin.
- the presence of chloride. Araldite 2020 resin contains a few percent of chloride which is enough to be detected by EDS, in contrast to organic particles.

The small sizes of the samples available for this study precluded the measurement of bulk porosity and permeability.

4. Results

4.1. Bulk composition and TOC

The samples are mainly composed of quartz, calcite, ankerite, muscovite, kaolinite, albite and pyrite, based on XRD quantification (Table 1, Fig. 3). Two examples of the XRD patterns are given in

Fig. 3. These mineral assemblages determined by XRD were confirmed by SEM observations, especially for clay minerals.

All Bowland-Hodder mudstone samples in this study are quartz-rich (>50 wt%) and clay-poor (<20 wt%) in contrast to sample B11, which is calcite-rich (>68 wt%) (Table 1). Kaolinite is the only clay mineral detected by XRD across all of the samples. The proportion of kaolinite is very low (<7 wt%) for all samples except B8 (18 wt%). Except for sample B11, all shale samples also contain various proportions of carbonates (from 6 to 71 wt%), such as calcite and ankerite. Quartz and calcite are also the most variable phases, with the least variation being seen in clay minerals (except B8 with 18% of kaolinite), muscovite, albite and pyrite (Fig. 4a).

Despite the variation in mineral proportions (Fig. 4a), all shale samples display quartz-rich and calcite-rich mineralogies, independently of their TOC (Fig. 4b). The TOC values vary from 0.5 to 6.1 wt% for all the shales and the majority of samples have a TOC higher than 2 wt%, which is usually considered the lower level for potential oil and gas plays (Table 1) (Charpentier and Cook, 2011). The TOC measurements were performed on centimetre-scale samples and are mean measurements, therefore local variability of organic matter content at smaller scales cannot be excluded.

4.2. Textural variability at the cm to μ m scale

Microtexture types were defined according to the thin section observations, on the basis of (a) the absence or presence of laminae, (b) lamina thickness, (c) grain type (mineralogy), (d) grain properties (e.g. size, orientation) and (e) the structure, content and nature of organic matter particles. Four main types were defined: unlaminate quartz-rich mudstone (type 1), interlaminate quartz-rich mudstone (type 2), laminated quartz-rich mudstone (type 3) and weakly interlaminate calcite-rich mudstone (type 4). For each microtexture type, one sample was selected to illustrate the microstructure. At the centimetre scale, the samples present various colors such as dark (B6), light to dark grey (B11, B1, B5, B8) or dark brown (B2), principally reflecting their organic matter contents (Fig. 5).

The samples show variations of texture due to the presence of laminae (B5, B8), fractures sealed by carbonates (B6, B8), carbonate and quartz clusters (B2), and brittleness with open fractures (B8).

4.2.1. Microtexture type 1: unlaminate quartz-rich mudstone (samples B1 and B6)

Sample B6 forms a homogeneous unit from the centimetre to the millimetre scales. Calcite veins are present in B6 (Fig. 5 d, j and 6 a, b). From the mm to μ m scales, the grains of quartz and carbonates are dispersed within a fine crystalline quartz cement. The sizes of clastic grains vary from 10 μ m to 50 μ m in diameter. The quartz grains are in contact, unlike the carbonates and other grains. They are rounded with irregular shape, in contrast to the ankerite and muscovite grains which are idiomorphic (Fig. 6 a, b). This microtexture type contains mainly lithoclasts and does not possess any bioclasts. Quartz grains are divided in two types: the primary quartz in the lithoclasts, which probably results from the deposition of sediment, and the secondary quartz included in the cement and which fills in holes in carbonate grains and organic matter. The organic matter particles are randomly located at the mm scale (Fig. 6b). They are mainly micrometre-scale isolated particles and submicron particles mixed in the cement at the μ m scale. Clay minerals (kaolinite) are located between the micrometre grains of quartz in the cement.

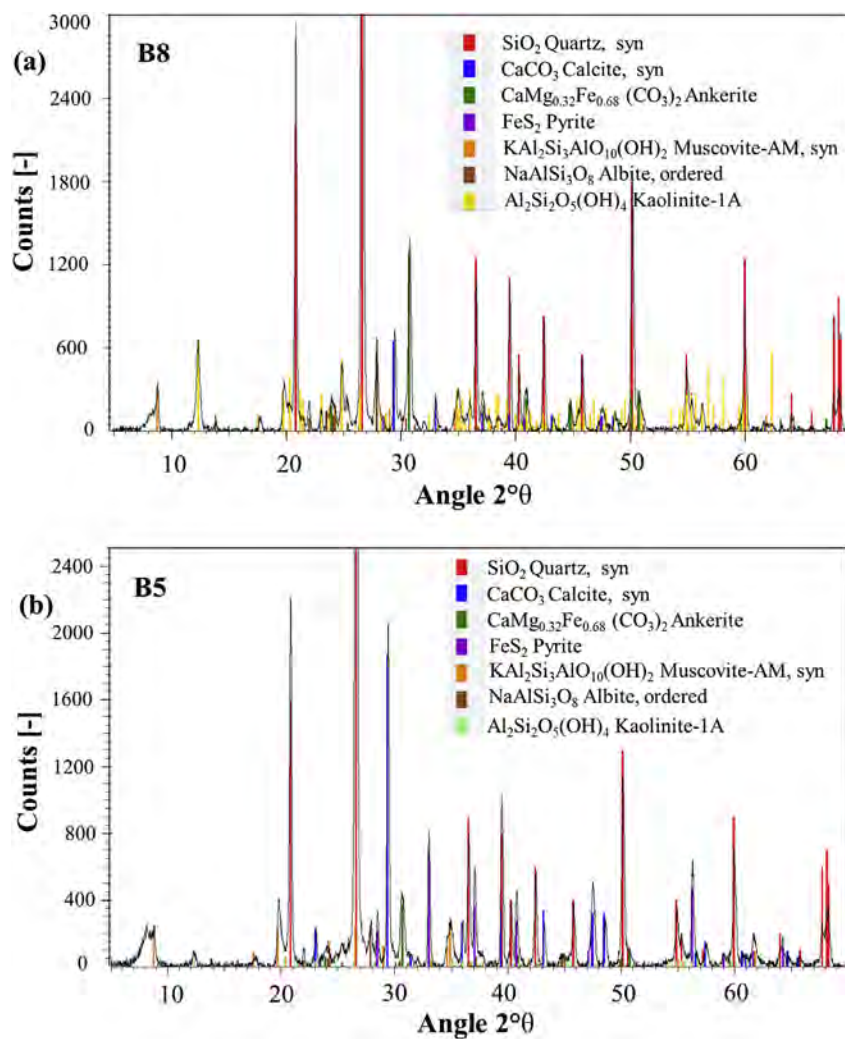

4.2.2. Microtexture type 2: interlaminate quartz-rich and pyrite-rich mudstone (B5, B2, B7)

At the centimetre scale, the interlaminate quartz-rich

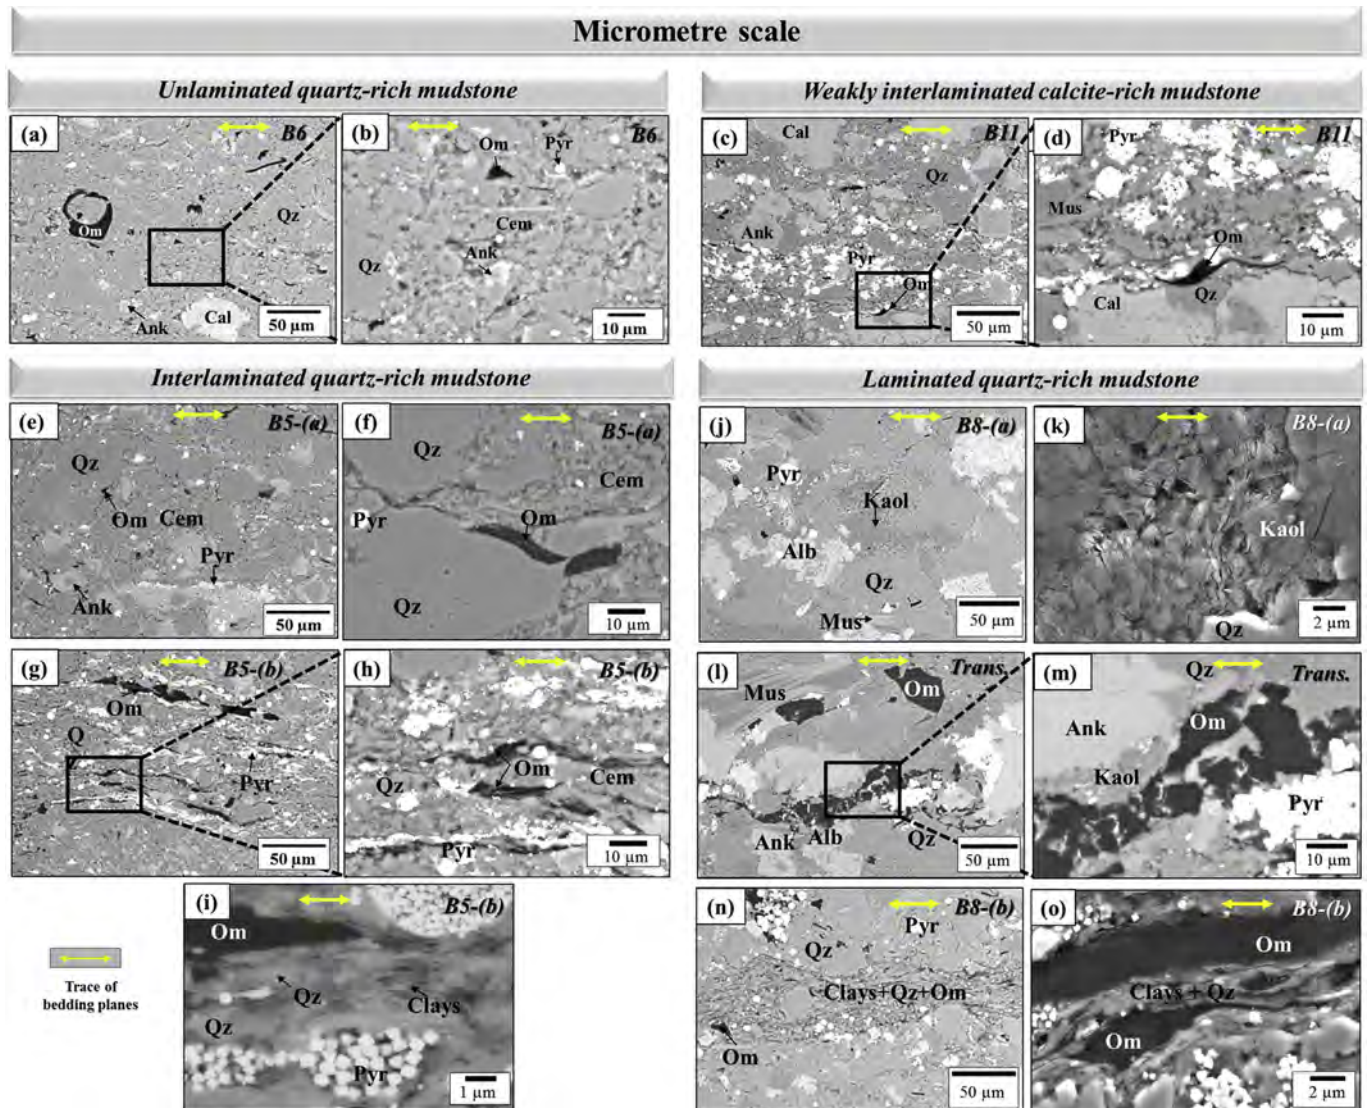

Fig. 6. Variability of mudstone microtexture types of Bowland Shale at the μm scale by back-scattered electron (BSE) images under SEM: (a,b) unlaminated quartz-rich mudstone, (c,d) weakly interlaminated calcite-rich mudstone, (e–i) interlaminated quartz-rich mudstone, (j–o) laminated quartz-rich mudstone. [Cal: calcite, Qz: quartz, Ank: ankerite, Om: organic matter, Qz: quartz, Pyr: pyrite, Cem: cement, Kaol: kaolinite, Alb: albite].

mudstone (Fig. 5 e–i) is heterogeneous due to the presence of periodic laminae, and the variation of their thickness and continuity. Two types of laminae are identified: (B5-a) grey quartz-rich lamina of millimetric thickness, and (B5-b) black organic and pyrite-rich lamina of around 100 μm thickness. The thickness of quartz-rich laminae is up to ten times that of the organic-rich laminae.

In B5-a (Fig. 6 e, f), the grains of quartz and carbonate display very various sizes (up to 100 μm). Quartz is particularly well-rounded and equant, unlike calcite which shows irregular shapes. Quartz and ankerite do not exhibit any evident shape preferred orientation. The largest calcite (>50 μm) and muscovite grains are elongate and oriented parallel to the bedding planes. The grains are held in a fine quartz cement in which detrital quartz grains are contiguous. Pyrite grains occur in randomly located framboid structures, with some assembled inside and/along the boundaries of calcite grains, parallel to bedding. The cement appears organic matter-poor at the μm scale.

In B5-b (Fig. 6 g–i), the grains of quartz and carbonates have qualitatively similar properties in terms of shape and orientation as

B5-a, but their size is significantly smaller (around 10 μm). The pyrites are assembled into framboids which form dense and elongate layers hundreds of μm long, and lying parallel to the bedding planes. These assemblages of pyrite are interlaced with elongate micrometric organic matter particles, confirmed by their opacity under crossed polars OM (Fig. 5i). Many submicron and elongate particles of organic matter are interlaced with submicron grains of quartz and clay minerals (Fig. 6 h, i).

4.2.3. Microtexture type 3: laminated quartz-rich mudstone (B8)

From the cm to the mm scales, the laminated quartz-rich mudstone is heterogeneous due to the presence of millimetre-size periodic laminae (Fig. 5 e, k and 6 j–o). The laminae are quartz- (B8-a) and organic-rich (B8-b) but their mineralogy is different than the samples B6 and B5, previously described. These laminae are intersected by ankerite and calcite veins that cross-cut the bedding (Fig. 5j). The transition between laminae is progressive or sharp, which could be interpreted as gradual and rapid changes of depositional conditions, respectively.

B8-a is composed of large grains of quartz, feldspars (albite),

muscovite, ankerite, calcite and framboidal pyrites. B8-a is strictly a siltstone and lithologically close to a sandstone, with grains of quartz and feldspar with a mean diameter between 50 and 100 μm , within a fine cement of quartz (Fig. 6j). Albite is altered and replaced by kaolinite, and filled by quartz cement, which suggests that this type of quartz is probably diagenetic (Bjorlykke and Egeberg, 1993; Schieber, 1996). B8-a contains large amounts of crystalline kaolinite (with no particular orientation), mixed with quartz and calcite grains in the cement (Fig. 6k). A few idiomorphic ankerite grains are present on and in replacement of calcite in veins. The organic matter is dispersed as submicron particles in the quartz cement, and in micrometric particles on pyrite boundaries. B8-a is organic-matter poor over the mm to μm scales. The concentration of large particles of organic matter increases in the transition of B8a to B8b (Fig. 6 l,m).

B8-b forms a heterogeneous unit with a lower mean quartz grain size (<30 μm), and multiple sizes and aspects of organic matter particles (Fig. 6 n, o). B8-b is feldspar-poor. The organic matter particles are present as very large (up to 100 μm) and elongate particles in the cement, orientated parallel to the trace of bedding, and as submicron particles between clay minerals (Fig. 6 n,o). The clay minerals are arranged into localized and discontinuous elongate lenses approximately 50 μm thick.

4.2.4. Microtexture type 4: weakly interlaminated calcite-rich mudstone (B11)

At the cm scale, the weakly interlaminated calcite rich microtexture type looks homogeneous (Fig. 5f). However, from the mm to the μm scales, irregular and discontinuous laminae are observed: (B11-a) calcite-rich laminae, and (B11-b) pyrite-rich laminae (Fig. 6 c, d). B11-a lamella are approximately millimetre thick and mainly composed of detrital calcite, authigenic calcite cement, ankerite, quartz and pyrite (Fig. 6 c, d). A small amount of clay minerals (kaolinite, but illite was also detected) is also present between the calcite and quartz in the cement. A few submicron organic matter particles are present in the cement without any preferential orientation at the μm scale. B11-b is composed of pyrite, phyllosilicates, quartz cement and orientated submicron-sized organic matter particles parallel to the trace of bedding. The framboidal pyrites form elongate and discontinuous layers, also aligned along the bedding trace with thicknesses varying from a few tens of μm to 100 μm . The quartz grains are divided into roughly equidimensional rounded grains and cement which fills the interstices between calcite grains.

4.3. Characterization of organic matter particles

An inventory of the different types of organic matter particles is shown in Fig. 7.

In the range of all mudstone samples, the organic matter particles are divided into four main types, as a function of their size and shape, the presence of macropores and their location:

Om1: micrometric particles. These particles are divided in two sub-types according to the presence or absence of macropores: Om1-a are organic matter particles of micrometric size and mainly equant and rounded, without macropores at the μm scale (Fig. 7a), and Om1-b which are organic matter particles of generally more than 10 μm size, with random shape and macropores at the μm scale (Fig. 7b). They are partially cemented by quartz and calcite. Their shapes and the presence of macropores suggest that they probably result from primary deposits of algal cysts (Leckie et al., 1990; Schieber, 1996). Om1-b pores are filled by diagenetic quartz (Schieber et al., 2000).

Om2: micrometre layers (Fig. 7c). Om2 is structured in dense layers (20–200 μm) parallel to the bedding trace and divided into a

multiple set of lamellar and fibrous structures with a length up to a few hundred μm . It does not contain macropores. Pyrite is commonly present inside and on the boundaries of Om2 layers. Om2 is sometimes combined with Om1-a.

Om3: submicron particles between quartz and clays (Fig. 7 d). Om3 is composed of very small and elongate organic matter particles lying parallel to the bedding trace, in the quartz cement or in the clay matrix. Their orientation and shape suggest that they come from the same primary deposit as Om2.

Om4: organic matter in oversize (larger than average) pores (Fig. 7e). Om4 is present in abnormal and very irregular macropores larger than 10 μm . In samples B5 and B11, the shapes of these features could suggest that they result from mineral dissolution during burial, which allows them to behave as preferential pathways for organic matter during maturation. However, no gradual concentration of particular element deposits were found around these oversize pores to confirm this hypothesis.

4.4. Diagenetic precipitation of carbonate veins

Carbonate (calcite and ankerite) veins are present in samples B2, B4, B6 and B8. Most veins lie either perpendicular (B4, B6, B8) or parallel to bedding (B2, B8) (Fig. 8).

A few inclined veins are also found in sample B6 (Fig. 5j). These veins are 50–300 μm thick and a few centimetres long. Veins occur in a small number of thick fractures in B6 and B2 and in a set of abundant and narrow fractures in sample B8, separated by a few ten μm . The veins contain micrometre vertical and horizontal fractures in sample B6 (Fig. 8b). Fig. 8 c–e shows that the calcite veins cross micrometric organic matter particles (Om1).

Ankerite and chlorite have partially replaced calcite in the veins of B8 and B6. Moreover, quartz cement is seen to have filled voids in calcite veins (Fig. 8b), demonstrating that quartz cementation has occurred after veining or that quartz co-precipitated with calcite (Fisher and Byrne, 1987; Fischer et al., 2009). Vein boundaries are sometimes associated with chlorite minerals in the laminated facies (B8) (Fig. 9 a, b).

Where present, chlorite occurs as micrometric crystals around the margins of the calcite veins and within the quartz cement between feldspars and kaolinite (Fig. 9 a, b). The crystals are most commonly oriented parallel to the bedding planes. Their location around the veins suggests a formation subsequent to or contemporary with veining.

The calcite veins are partially filled by metal oxide deposits such as rutile, especially in sample B8 where the frequency of calcite veins is highest (Fig. 10 a, b).

The rutile inclusions have irregular and smooth shapes with diameters varying between 2 and 10 μm (Fig. 10b). These inclusions are also present on the boundaries of veins, in the quartz cement around the veins and as trace minerals within aluminosilicates, especially in kaolinite. Titanium is also present as detrital rutile minerals in the cement (Fig. 10c). The presence of such titanium inclusions in calcite veins proves an authigenic formation by precipitation after veining. These vein inclusions also suggest that Ti-bearing fluid transport event occurred.

4.5. Mineral alteration and neoformation

4.5.1. Association of crystalline kaolinite and altered albite

Primary deposits of clays in shale are usually oriented with basal planes sub-parallel to the trace of bedding planes due to sedimentation and compaction. However, the kaolinite in sample B8 has no preferred orientation and displays large crystalline assemblages (greater than 10 μm) that are often associated with feldspars and quartz cement in quartz-rich laminae (Fig. 11 a, b).

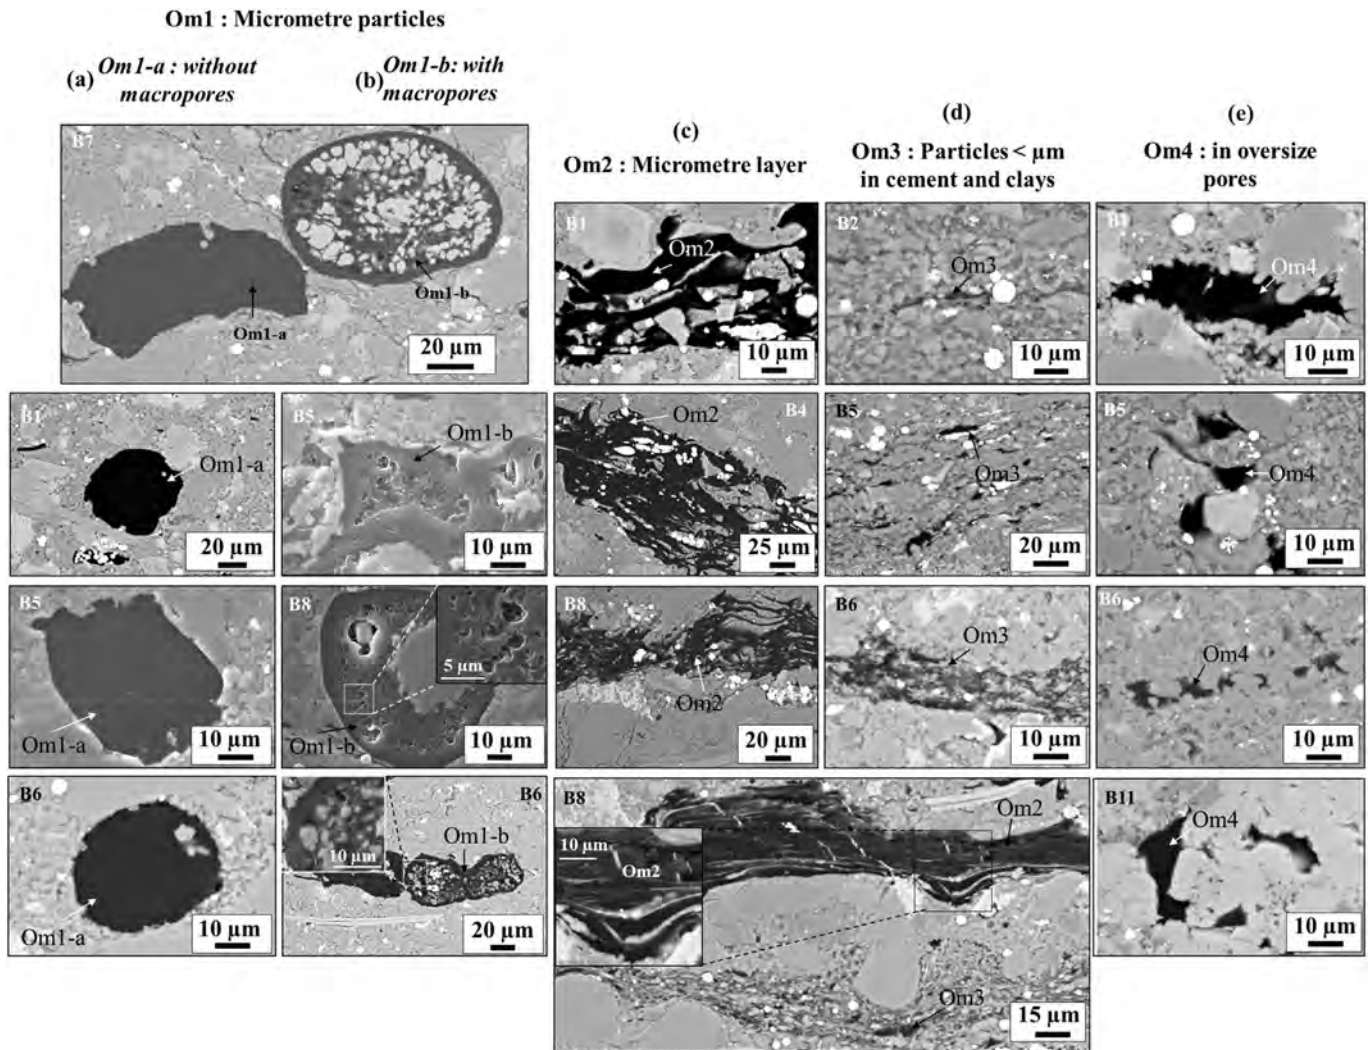

Fig. 7. Various types of organic matter particles in Bowland shale under SEM: (a) micrometric particles of organic matter without macropores (Om1-a); (b) micrometric particles of organic matter with macropores (Om1-b); (c) micrometric layers of organic matter (Om2); (d) Sub-micrometric organic matter particles in cement (Om3); (e) organic matter in oversize pores.

Albites are typically heavily altered, contain many holes partially filled by authigenic quartz, and are bordered by multi-micrometre “booklets” of kaolinite and muscovite. The frequent association of altered albite with authigenic kaolinite and quartz suggests the neoformation of kaolinite from the alteration of albite during burial (Oberlin and Couty, 1970; Boles and Franks, 1979).

4.5.2. Idiomorphic ankerite

All shale samples except B2 contain, in various proportions and sizes, very well-formed crystallites of ankerite within the quartz cement, and mixed with calcite in veins. An example from sample B1 is shown in Fig. 12a. The size of the ankerite crystals qualitatively varies from a few μm (B7, B8) to 20 μm (B1, B6, B5, B9, B10). The strongly idiomorphic shapes of ankerite and their random orientations suggest that they developed authigenically. Moreover, they crosscut the calcite veins, demonstrating that the ankerite crystals were formed subsequent to veining (Fig. 12 b, c). Quartz cement composed of multi-micrometric grains of quartz partially fills the calcite veins, and crosscuts or surrounds ankerite (Fig. 12 a, d), suggesting that ankerite formation was probably followed by a period of quartz cementation.

4.6. Variability of fractures

Knowledge of the fracture network is important for effective hydraulic treatment design (Gale and Holder, 2010). Natural fractures and mechanical discontinuities in general can affect the propagation of hydraulic fractures through delamination for example, which eventually causes opening of pathways under high pressure (Warpinski and Teufel, 1987; Gale et al., 2007; Gale and Holder, 2010).

In this study, four types of fractures were found in Bowland shale:

F1: Mineral-sealed fractures (Figs. 8 and 13a). During post-compaction diagenesis, veins were formed as fractures filled with precipitated solids. In this case, the vein-filling phase is mainly calcite and ankerite, and can be termed calcite-sealed fractures. Note that the calcite veins previously described and the calcite-sealed fractures correspond to the same features. The majority of these sealed fractures lie perpendicular to bedding planes but inclined and horizontal fractures are also present. Gale and Holder (2010) showed that Barnett and New Albany shale (USA) samples with natural calcite-sealed fractures display tensile strengths less than 50% of that measured in samples without veins, and will

always tend to fail along available fracture planes. Lee et al. (2015) also demonstrated that fractures preferentially refract in the middle of calcite veins during semicircular bending tests on Marcellus Shale. Calcite-sealed fractures are considered to be weak joints because calcite grows between non-carbonate grains without any cement with the border grains (Gale and Holder, 2010; Lee et al.,

2015). Despite this tendency, Montgomery et al. (2005) considered that natural calcite-sealed fractures are insignificant for production in the Barnett shale (USA). Shales have usually undergone large amounts of compaction and porosity loss during progressive burial. Thus when vertical planar veins crosscut bedding their formation must have occurred post-compaction strain, when the rock

became sufficiently brittle to host fractures.

F2: Natural fractures partially filled by organic matter (Fig. 13 a, b, c, d). The majority of these fractures lie parallel to bedding planes (Fig. 13 b, c), although a significant proportion is inclined or vertical (Fig. 13 a, d, e, f). The horizontal fractures are present in the cement along the boundaries of quartz, calcite, feldspar and mica grains, sometimes crosscutting calcite grains and detrital muscovite. They occur either as discontinuous thin, individual fractures from 1 to 2 µm aperture, continuous and individual fractures of 5–6 µm aperture (Fig. 13 b), or as a set of thin fractures forming a multi-micrometre fracture assemblage (Fig. 13 c) in the prepared samples. Sample B8 contains the greatest number of calcite veins examined, and a significant number of vertical fractures partially filled by bitumen and impregnation resin (Fig. 13 e–g). The bitumen-bearing fractures mostly lie within the organic-rich laminae, but some are also located along and inside calcite veins in the quartz-rich laminae (Fig. 13 e–g). Their aperture is very variable, from <1 µm to approximately 25 µm at the studied scales. A small number of fractures show brecciated aspects with a locally higher concentration of small grains of quartz and broken grains of micas, ankerite and calcite (Fig. 13 d).

F3: Fractures filled by resin (Fig. 13 h). These fractures are located in and on the boundaries of calcite veins, and in the quartz cement. Some of these fractures cut quartz and feldspars, and show brecciated aspects. These fractures transect calcite veins in sample B2, demonstrating that their formation was subsequent to veining. Because they became filled by resin and the sample was cut after impregnation, they could have been formed whilst the rock at depth. They are also likely to have been formed by release of in-situ stresses during extraction from the borehole. Their apertures are generally larger (several micrometres) and more homogeneous than the bitumen-filled fractures. Many of these fractures are

connected (Fig. 13 h).

F4: “Empty” fractures (Fig. 13 b, g, i, j). Many of these fractures are horizontal, but vertical empty fractures are also observed. The horizontal empty fractures are located alongside or at the ends of organic matter particles (Om3) in the cement (Fig. 13 b), and at the boundaries of quartz or micas (Fig. 13 i, j). Their aperture is generally less than 1 µm. Fig. 11 j shows a high rate of occurrence of these fractures in the cement of B8, but they appear discontinuous and unconnected in 2D. Empty fractures also occur as a continuation of bitumen-filled fractures (Fig. 13 e, g), following the direction of pre-existing fractures and cleavages in calcite veins. They may have been produced by stress release during sample recovery from depth, or during handling, but were too small to give easy access to the impregnation resin.

5. Interpretation and discussion

5.1. Variability of microtexture

5.1.1. Implications for anisotropy and mechanical properties

The samples analyzed in this study display heterogeneous microstructures in terms of mineralogy, texture and TOC (Table 1, Figs. 3 and 4). Even though the mean mineral proportions determined by XRD may be similar for all shale samples studied (e.g. all are quartz-rich), they have very variable microstructures owing to the presence of variable developments of periodic laminae from the µm to mm scale, which should be expected to cause strong and variable mechanical anisotropy. The comparison between the XRD, TOC, OM and SEM results thus emphasises the fact that XRD results alone are insufficient to classify the different shale samples. Petrographic observations can sometimes be superior to bulk analyses because the local variability of a range of parameters can be

variations of individual sedimentary facies (Cuss et al., 2015).

It is relatively well-known that the mechanical properties (strength, elastic properties, dilatancy, creep ...) of shale are dependent on several parameters such as mineralogy, grain shape and orientation, or porosity related to the orientation of bedding (Bjørlykke and Høeg, 1997), and become apparent during unconfined or triaxial compression testing, or during thermal stimulation (Niandou et al., 1989; Ibanez and Kronenberg, 1993; Naumann et al., 2007; Gutierrez et al., 2008; Sone and Zoback, 2013; Masri et al., 2014; Cuss et al., 2015; Bonnelye et al., 2016a,b; Keller et al., 2017). The samples of Lower Bowland shale studied here are very anisotropic with a mineralogic banding plus shape and crystallographic preferred orientation of clays (organic-rich laminae), pyrite and individual organic particles, contrasting with silica-rich laminae. Furthermore, the development of a vertical spatial variability of microtexture types with variable mineralogy and texture in the sequence of Lower Bowland Shale also induces a coarser vertical degree of development of anisotropy. The laminae have different thickness, from the μm to mm , and may be continuous or discontinuous, which can lead to local variations of mechanical behavior. Laminae and microtexture changes induce discontinuities and weak regions that can focus stress concentrations according to corresponding variations in elastic moduli (Lan et al., 2010; Amann et al., 2011), and may provide preferential ways for fracture growth. Variable degrees of development of clay mineral preferred orientation were observed, especially in the laminated microtexture, ranging from kaolinite mineral grains that are randomly and horizontally arranged in quartz-rich and organic-rich laminae of the laminated mudstones, to laminae in which clay crystallites are strongly oriented as a result of mechanical compaction.

The studied Lower Bowland shale samples therefore display very anisotropic microstructures, but the degree of anisotropy varies with the microtexture, mainly manifested as a variability of clay orientation and the thickness of laminae.

5.1.2. Primary depositional variability

The Lower Bowland shale samples correspond to hybrid shale in which elements of organic-pyrite-rich mudstone, organic sandstone (quartz-rich laminae of B8 for example) and organic siltstone are intimately interlayered. Turbidite facies have also been found in samples of Bowland shale retrieved from other boreholes (Waters and Davies, 2006; Gross et al., 2015). The description of Lower Bowland microfacies herein has shown a wide variation of clastic and carbonate particle sizes and modal proportions, and also of TOC values. These observations reflect a primary variability of depositional controls within the basin, arising from glacio-eustatic fluctuations and tectonic events (Gross et al., 2015; Gawthorpe, 1987; Holdsworth and Collinson, 1988; Fraser and Gawthorpe, 2003; Waters and Condon, 2012; Gross et al., 2015).

5.2. High TOC and TOC variability in Lower Bowland shale

The majority of the studied shale samples have TOC higher than 2 wt%, between 1.1 and 6.1 wt% and with an average of 2.88 wt%. The presence of organic matter-rich samples confirms analyses reported in other recent studies (DECC, 2010; Charpentier and Cook, 2011; IGas, 2012; Andrews, 2013). However, the alternation between organic matter-rich and -poor laminae probably acts to decrease the mean value of TOC and clay content at the cm and larger scales. As a consequence, the laminated samples (B7, B8) are classified as low TOC (<2 wt%) shales despite the presence of organic matter-rich laminae. In the same way, the local TOC values at the mm scale could be much higher than the results obtained by bulk TOC measurements at the cm scale for the samples displaying interlaminated facies (B5). SEM observations highlight the fact that

evaluated (Hackley and Cardott, 2016). Key properties such as organic content, gas content and strength depend on such local

Fig. 13. Fractures (arrows) in Bowland shale. BSE images of: (a) calcite-sealed fracture F1; (b) horizontal bitumen-filled fracture (F2) and empty fracture (F4) along F2; (c) assemblage of thin F2; (d) horizontal and vertical F2; (e) F1 crossed by a bitumen-filled and empty fractures; (f) inclined F2 crossing F1 corresponding to the magnified view of (e); (g) vertical empty fracture in F1 in the continuity of F2; (h) resin-filled fractures (F3); (i) empty fractures along organic matter and micas; (j) empty fractures at the extremities of organic matter particles (Om3) in quartz cement.

the Bowland shale samples in this study contain narrow units (<1 mm) of higher-than-background TOC (but not quantified in this paper) from the μm to the mm scale, and qualitatively confirms the conclusions of Andrews (2013). Similarly, Maynard et al. (1991) measured TOC of two thin Namurian shales from the Upper Carboniferous basin of Northern England with local TOC up to 10 to 13 wt%, but these bands were interbedded within strata of 2–3 wt% TOC, which leads to a lower mean TOC.

5.3. Quartz-rich and clay-poor Lower Bowland shale

In this study, all shale samples examined are quartz-rich and clay-poor in comparison with some other samples of Bowland shales (Andrews, 2013; EIA 2015a,b; Gross et al., 2015; Ma et al., 2016). Moreover, the clay minerals detected here are mainly kaolinite, whereas other Bowland shale samples may also contain a significant quantity of illite (Gross et al., 2015; Ma et al., 2016) and mixed layer minerals (Gross et al., 2015). In general, shale is predominantly composed of very fine grained particles within an indurated matrix, with or without laminations (Spears, 1980; Bates and Jackson, 1984; Jackson et al., 2007; Passey et al., 2010; Sondergeld et al., 2010). Shale is formed by the compaction of clay minerals together with mud or silt-sized framework minerals (Bates and Jackson, 1984), and associated with a substantial loss of porosity and development of fissility. A simple definition of shale for gas plays refers to a productive fissile rock containing a significant amount of organic matter from fine-grained rocks which can be carbonate, silica or clay-rich rocks such as the Haynesville, Barnett, Woodford, and Marcellus shales (USA) (Milner et al., 2010; Hammes et al., 2011; Chalmers et al., 2012). Loucks and Ruppel (2007) described shales containing less than one-third clay minerals as siliceous mudrocks. Various definitions are found in the literature (e.g. Ougier-Simonin and Renard, 2016) and the finest grains do not necessarily correspond solely to clay minerals. In the present study, the fine and detrital microstructure of all samples also includes various types of organic matter particles, giving mean whole-rock TOC higher than 2 wt%. Our samples were thus considered as shales even if their clay contents were to be less than 20 wt%. In these rocks, the detrital grains are mixed in a quartz cement rather than a clay matrix, although lenses of clays were also identified in some samples (B5, B8). A low proportion of clay minerals (<35%) is considered to be an advantage to facilitate hydraulic fracturing and gas extraction, because high proportions of tectosilicates (quartz), carbonates and other non-swelling minerals act to limit the rock ductility and to enhance brittleness (Jarvie, 2014; Raji et al., 2015). However, Montgomery et al. (2005) and Ross and Bustin (2008) find an inverse relation between silica content and porosity in some areas of Muskwa and Besa River shales, demonstrating that silica content and ability to fracture should be considered alongside other characteristics while estimating potential resource capacities.

Canadian shale from the Muskwa and the Lower Besa River shales in northern British Columbia display similar bulk mineralogy to the Bowland samples used in this study (Ross and Bustin, 2008). They are silica-rich (from 58 to 93 wt%), TOC-rich (up to 5%), and the lowest quartz contents are associated with carbonates such as dolomite (around 40 wt%). Moreover, clay minerals represent only 1 to 25 wt%. As with Besa River and Muskwa shales, Bowland shale samples are composed substantially of detrital silica, but subsequent cementation and replacement crystallization of quartz can make the identification of primary silica grains difficult. Consequently, the origin of some of the silica (quartz) is difficult to explain for the Bowland shale samples presented here. The presence of organic matter derived from algal cysts demonstrates a marine depositional environment, but the absence of siliceous

fossils such as radiolaria and other microfossils suggests that the high quartz content is not due to biogenic activity.

5.4. Fluid passage and temperature-driven reactions during burial

Using the cross-cutting principle, different events identified can be qualitatively ordered in time sequence. There are (a) feldspar alteration and neoformation of kaolinite, (b) calcite veining, (c) ankeritization of calcite, (d) quartz cementation and (e) organic matter migration through fractures. These features demonstrate a likely late or post diagenetic circulation within or passage of fluids through these Bowland shale samples, accompanied by veining and mineral alteration at low temperatures. It was followed by a second circulation of hydrocarbon-bearing fluids at higher temperatures. These events were not necessarily followed precisely one by the other, but could be partially concurrent in some cases. The description of these events (below) provides preliminary qualitative data on the burial conditions and maturation of Bowland shale in the Preese-Hall-1 borehole, but these conditions must be further studied on a significant quantity of samples from various locations before being generalized for the Bowland shale basin.

5.4.1. Veining episode

Calcite-veins (F1) crosscut all types of laminae, indicating a displacement of fluids subsequent to primary sediment deposition and compaction. Silica-bearing fluids are presumably expelled from greater depths in the sediment pile as a result of the final stages of compaction and diagenetic reactions. The general planar orientation of veins normal to the compaction fabric demonstrates that the veining occurred in the fully-compacted and indurated host-rock. Experimental observations of mechanical compaction and study of natural shale-bearing basins shows that most compaction is completed by much less than 1 km of burial (Rutter et al., 2017). The orientations observed of the calcite veins suggest a simple, transversely isotropic stress field arising from compaction under the weight of overburden. In the range of samples studied, the majority of veins lie perpendicular to bedding planes, forming a vertical polygonal network (although some horizontal and inclined veins are present), indicating that the maximal principal stress arose from the vertical load. Compaction-induced pore fluid overpressuring occurs when the fluid pressure rises to become very close or equal to the least principal stress during burial. In transversely isotropic loading there is little difference between the least and the intermediate principal stresses in the horizontal plane. In low permeability rock such as shale, fluid cannot be rapidly expelled from the pores, therefore pore pressure may rise sufficiently to cause vertical hydrofracture formation, perhaps assisted by horizontal crystallization pressure if minerals grow in the veins from locally supersaturated solutions. The possibility of penecontemporaneous fracture along bedding planes can also arise, allowing the formation of horizontal calcite veins in shale owing to the lower fracture toughness for bedding-parallel fracture. It can result of the bedding anisotropy coupled with a low differential stress as a consequence of creep deformation, also promoted by a high pore fluid pressure (Stoneley, 1983). However, the absence of organic matter inside the calcite veins (at the μm scale), and the dominance of vertical veins suggest that a relatively high vertical principal stress suppressed significant formation of bedding-parallel veins. Horizontal calcite veins can also form in rocks via the Poisson ratio effect when differential stresses have been relaxed by creep and there is a degree of vertical depressurization through an erosional episode.

The Visean shales of the Bowland basin were deposited during the syn-rift stage of a Lower Carboniferous back-arc basin, and are restricted to graben and half-graben separated by platforms and

tilt-block highs (Leeder, 1982, 1988; Warr, 2000; Waters and Davies, 2006). The Namurian shales were deposited in the subsequent thermal subsidence stage (Leeder, 1988; Waters and Davies, 2006), which is emphasized at small scales with localized extension and compression episodes in the Pennine Basin in Northern England (Waters et al., 1994). Rocks of the Craven group, which includes Viséan and Namurian shales in the Bowland sequence elsewhere in the basin, was subjected to tectonic activity during the late Chadian to early Arundian and from the late Asbian until the early Brigantian stages. Evidence of hydrothermal precipitation is very poorly documented within the scientific literature on the Bowland sequence, and it is difficult to discern how long after deposition the carbonate veining occurred. Isotopic and dating measurements of calcite minerals would be required to resolve this question.

In shales, the formation of calcite veins usually occurs at temperatures between 20 and 60 °C at shallow to intermediate burial depths (up to hundreds of meters deep) (Al-Aasm et al., 1992), but formation of calcareous mineralization at up to 2.3 km depth has been inferred for some shale formations, such as the middle Devonian shale from the Appalachian plateau (USA) (Evans, 1995).

5.4.2. Clay minerals

Quartz-rich laminae within laminated facies contain significant quantities of altered albite, together with micrometric kaolinite with “booklet” shapes. Alteration of detrital albite to authigenic kaolinite in shale is commonly due to a temperature-dependent reaction and pore fluid interactions during burial (Boles and Franks, 1979; Tieh et al., 1986). This reaction occurred in Wilcox shale at temperatures between 100 and 120 °C (Boles and Franks, 1979). In the present study, the samples show that a first type of kaolinite resulted from primary deposition (oriented crystals in organic-rich laminae) and a second type (randomly oriented authigenic kaolinite in quartz-rich laminae) that corresponds to the alteration of feldspars (albite).

5.4.3. Ankerite neoformation and quartz cementation

At temperatures higher than 100 °C, iron and magnesium in solution may react with kaolinite to produce chlorite, and/or with calcite to produce ankerite (Boles and Franks, 1979). Iron and magnesium generally originate from illitization. Ma et al. (2016) found 23 wt% of illite and 2 wt% of kaolinite in Bowland shale sourced from the Swinden borehole in the west of the Bowland basin. Illite is not present in the XRD analyses of the samples studied here, whereas a few illite grains are seen in a small number of SEM images (in B5 for example). As a result, the sources of iron and magnesium are not yet understood. In general, ankerite is more abundant in sequences of thin sandstones associated with thick shale layers, than it is in thick sandstone layers (Boles and Franks, 1979). This generalization was confirmed to be the case for the Bowland shale in Preese Hall-1 by the laminated and inter-laminated micro-texture types, and agrees with the observations and inferences of Waters and Davies (2006) and Andrews (2013). Their strong crystallographic forms and their location in veins as a calcite substitute suggest an authigenic origin and formation subsequent to veining.

Quartz cement partially infills calcite veins and crosscuts authigenic ankerite minerals, revealing that quartz cementation was a late event, occurring after veining and ankerite formation. The presence of veins, crystalline quartz cement and crystalline kaolinite, plus Ti and Fe oxides inside veins, may also imply a passage or circulation of fluids through these laminae, and may partially explain the feldspar alteration to kaolinite.

The quartz cementation is particularly present in quartz-rich laminae of the laminated mudstones which are siltstone to sandstone according to their grain size, and in the unlaminated

mudstone samples. In relatively porous, quartz-rich sandstones, large volumes of water can pass through the pore system, permitting cementation in areas where pressure solution is absent (Boles and Franks, 1979). Siltstone, sandstone and mudstone are usually studied independently but in our case, they are dispersed periodically and vertically throughout the sample set. In the Wilcox sequence in Texas (USA), the majority of pore waters derived from the original compaction of shale moved through the (more permeable) interbedded sandstones, despite shales representing the majority of the stratigraphic section (Burst, 1969). Waters passing from shales to siltstone and sandstones during diagenesis should facilitate chemical component transfers, which may enable the formation of sandstone cement (Curtis, 1978; Boles and Franks, 1979). The laminated mudstone microtextures of the Bowland shale samples presented here are composed of organic-rich laminae, wherein detrital grains are mixed in a fine cement of quartz and clay lenses, interbedded with quartz-rich laminae, which appear similar to quartz-cemented siltstone and sandstones. These quartz-rich laminae are composed of large grains of quartz cemented by fine-grained quartz grains. Following a hypothesis of Curtis (1978), water could pass from the organic-rich to quartz-rich laminae and its transfer could facilitate the quartz cementation. The very low clay content in Bowland shale samples allows us to admit this hypothesis as possible. However, a low content of primary clay minerals does not necessarily mean that porosity and permeability are high enough to permit this process. Porosity and permeability data are few for Bowland shale (Andrews, 2013), but are commonly very low in shale formations (e.g. Rutter and Mecklenburgh, 2017), hence the latter hypothesis could also explain the quartz cementation. The SEM observations suggest that the quartz cementation occurs late, after the veining and ankerite formation (if there is only one period of cementation).

5.5. Organic matter migration during thermal maturation

5.5.1. Migration through fractures

The samples studied here show a high variability of fracture types, in terms of their content (carbonate, bitumen, resin, empty), orientation and size. The opening of fractures generated by the expansion of organic matter is traditionally thought to be caused by pore fluid overpressuring through organic decomposition and petroleum generation, which happens in the 80–150 °C temperature range (Bjørlykke, 2010; Kobchenko et al., 2011; Goult et al., 2012). Very low heating rates between 1 and 2 °C/Ma have been inferred, but sometimes reaching as high as 10 °C/Ma (Bjørlykke, 2010). The late bitumen-filled fractures F2 crosscut the shale microfabric, ankerite grains, quartz cement and carbonate veins, showing the migration of organic-matter occurred subsequently to the formation of all these features.

5.5.2. Fracture orientation

In shales in general, bitumen-bearing horizontal fractures are significantly more common than vertical fractures. For example, horizontal bitumen-filled fractures are found in the clay matrix of organic-rich laminae in the lower half of the Upper Devonian Dunkirk Shale alongside a smaller population of vertical bitumen-filled fractures (Lash and Engelder, 2005). These fracture populations also typify the Oligocene Frio shale (Capuano, 1993) and Upper Devonian Strachan shale in the Alberta basin (Marquez and Mountjoy, 1996) in the USA. The majority of their bitumen-filled fractures are oriented parallel to the bedding planes. This is an important initial anisotropy caused by the horizontal laminae and clay grain fabric and by many kerogen grains lying flattened parallel to bedding, which can correspond to Om2 and Om3 in our case. When interconnected, these horizontal fractures may aid the

migration of hydrocarbons into reservoir rocks (Momper, 1978; Rouchet (du), 1981; Talukdar et al. 1987; Ozkaya, 1988; Capuano, 1993; Marquez and Mountjoy, 1996; Lash and Engelder, 2005).

The Upper Devonian Strachan shale in the Alberta basin (USA) and the black shale of the Bluefish basin (Canada) also feature many horizontal fractures (Al-Aasm et al., 1992; Marquez and Mountjoy, 1996). Diagenesis generates vertical compaction and smaller induced horizontal stresses during burial, but the horizontal stresses may become larger than the vertical stress as a result of differential stress relaxation during creep, coupled with removal of overburden through erosion, which will facilitate the formation of late horizontal fractures along bedding planes (Turcotte and Schubert, 2002; Rouchet (du), 1981; Spencer, 1987).

The Bowland shale samples contain horizontal bitumen-filled (F2) and empty fractures (F4) which are very similar to those observed by Lash and Engelder (2005). However, the samples also contain a significant number of vertical bitumen-filled fractures, especially in dense calcitic-vein areas as in sample B8, and unlike the North American shales described above. Moreover, the vertical bitumen-bearing fractures (F2) systematically crosscut calcite veins and isolated calcite grains in the cement. These late, radially distributed, vertical bitumen-bearing fractures were interpreted to have formed from fractures branching from pre-existing calcite veins owing to reduced fracture toughness at their margins.

6. Conclusions

In this study the variability of the microstructure of the Lower Bowland shale was highlighted from the cm to μm scale using the traditional techniques of microscopy combined with XRD and TOC measurements. The samples show a high variability of: (i) microtexture types (unlaminated, interlaminated and laminated quartz-rich mudstones and weakly interlaminated calcite-rich mudstone), (ii) mineralogy, (iii) TOC (from 0.5 to 6.1 wt%), (iv) organic-matter particles (micrometric particles with and without macropores, multi-micrometre layers, submicrometre particles in the cement and particles in oversize pores), and (v) fractures which are organized in a complex network (calcite-sealed, bitumen-filled, empty and resin-filled fractures).

The majority of samples are quartz-rich and high TOC (>2 wt%). Some samples have low overall TOC but their microstructure shows local cyclicity between organic-rich and organic-poor laminae. This confirms the presence of narrow (<1 mm) and periodic, qualitatively organic-rich deposits in Bowland shale as has been previously suggested in the literature. The low clay content (<20 wt%), the high detrital and cemented quartz content (>50 wt%), and the presence of a complex and multi-scale fracture network support the developing interest in the Lower Bowland shale as a potential hydrocarbon resource.

The planar geometry of the vertical calcite veins means that the rock was already compacted and lithified before the carbonate-sealed fractures could form. Subsequently, mineral replacements and authigenic growths of clay minerals and secondary carbonate grains (calcite and ankerite) formed. Later, horizontal bitumen-bearing fractures provided routes for hydrocarbon migration and may have formed as maximum principal stress became horizontal as a result of stress relaxation during creep coupled with erosional offloading. The vertical bitumen-bearing fractures were interpreted as being due to the influence of weak joints generated by the previous carbonate veining episode, which increases the brittleness of the shale. The microstructural and mineralogical heterogeneities in areas heavily affected by veins may have preferentially facilitated formation of open fractures (resin-filled and empty) during specimen recovery and handling.

The identification of various microtexture types and their

heterogeneities in terms of mineralogy and structure (fractures, laminae) will aid the selection of specific types of samples for 2D and 3D high-resolution imaging in the cement and clay lenses, and for geomechanical characterisation. In the same way, the description of the various organic matter particles should guide the selection of key particles for characterization of the pore network within kerogen and bitumen-filled fractures.

Evidence of a range of geological episodes such as carbonate-veining, feldspar alteration to kaolinite, ankerite neoformation and bitumen-driven fracturing highlight periods of fluid passage or circulation within the Bowland sequence and temperature-driven reactions occurring during burial, for over the temperature range between approximately 30 and 150 °C. The evidence presented here provides new aspects to aid understanding of the geological history of the Lower Bowland sequence, which should aid in the development of a more generalized understanding of the sequence through future studies across larger sample quantities.

In future studies of Lower Bowland Shale microstructure, a regular separation distance between the samples should be taken and further observations of the cement should be made to evaluate the connectivity of the various fractures, especially the numerous horizontal micrometre-scale empty fractures F4, and to make a better estimation of mineralogy and modal fraction of clays present.

Acknowledgments

The following people contributed to the completion of this paper: Dr Katie Cunnea, Dr Alex C. Leung, Dr Sara Nonni and Mr Paul Waters. We thank the British Geological Survey (Nottingham, UK) for the Bowland Shale samples. This project has received funding from the European Union's Horizon 2020 716 Research and Innovation Programme under the ShaleXenvironmentT project, (grant no. 640979), with facilities and support also provided by the Research Complex at Harwell, funded in part by NERC (NE/M001458/1) and EPSRC (EP/I02249X/1). Data Statement: representative research data is presented in the images and graphs in this manuscript.
